Dear Author

Here are the proofs of your article.

- You can submit your corrections **online** or by **fax**.

- For **online** submission please insert your corrections in the online correction form. Always indicate the line number to which the correction refers.

- Please return your proof together with the permission to publish confirmation.

- For **fax** submission, please ensure that your corrections are clearly legible. Use a fine black pen and write the correction in the margin, not too close to the edge of the page.

- Remember to note the journal title, article number, and your name when sending your response via e-mail, fax or regular mail.

- **Check** the metadata sheet to make sure that the header information, especially author names and the corresponding affiliations are correctly shown.

- **Check** the questions that may have arisen during copy editing and insert your answers/corrections.

- **Check** that the text is complete and that all figures, tables and their legends are included. Also check the accuracy of special characters, equations, and electronic supplementary material if applicable. If necessary refer to the *Edited manuscript*.

- The publication of inaccurate data such as dosages and units can have serious consequences. Please take particular care that all such details are correct.

- Please **do not** make changes that involve only matters of style. We have generally introduced forms that follow the journal's style.
  Substantial changes in content, e.g., new results, corrected values, title and authorship are not allowed without the approval of the responsible editor. In such a case, please contact the Editorial Office and return his/her consent together with the proof.

- If we do not receive your corrections **within 48 hours**, we will send you a reminder.

Please note

Your article will be published **Online First** approximately one week after receipt of your corrected proofs. This is the **official first publication** citable with the DOI. **Further changes are, therefore, not possible.**

After online publication, subscribers (personal/institutional) to this journal will have access to the complete article via the DOI using the URL:

```
http://dx.doi.org/10.3758/s13428-020-01393-5
```

If you would like to know when your article has been published online, take advantage of our free alert service. For registration and further information, go to: http://www.springerlink.com.

Due to the electronic nature of the procedure, the manuscript and the original figures will only be returned to you on special request. When you return your corrections, please inform us, if you would like to have these documents returned.

The **printed version** will follow in a forthcoming issue.

75	Abstract	In the previous decade, dozens of studies involving thousands of children across several research disciplines have made use of a combined daylong audio-recorder and automated algorithmic analysis called the LENA® system, which aims to assess children's language environment. While the system's prevalence in the language acquisition domain is steadily growing, there are only scattered validation efforts on only some of its key characteristics.

Here, we assess the LENA® system's accuracy across all of its key measures: speaker classification, Child Vocalization Counts (CVC), Conversational Turn Counts (CTC), and Adult Word Counts (AWC). Our assessment is based on manual annotation of clips that have been randomly or periodically sampled out of daylong recordings, collected from (a) populations similar to the system's original training data (North American English-learning children aged 3-36 months), (b) children learning another dialect of English (UK), and (c) slightly older children growing up in a different linguistic and socio-cultural setting (Tsimane' learners in rural Bolivia). We find reasonably high accuracy in some measures (AWC, CVC), with more problematic levels of performance in others (CTC, precision of male adults and other children). Statistical analyses do not support the view that performance is worse for children who are dissimilar from the LENA® original training set. Whether LENA® results are accurate enough for a given research, educational, or clinical application depends largely on the specifics at hand. We therefore conclude with a set of recommendations to help researchers make this determination for their goals.

Abstract

In the previous decade, dozens of studies involving thousands of children across several research disciplines have made use of a combined daylong audio-recorder and automated algorithmic analysis called the LENA® system, which aims to assess children's language environment. While the system's prevalence in the language acquisition domain is steadily growing, there are only scattered validation efforts on only some of its key characteristics. Here, we assess the LENA® system's accuracy across all of its key measures: speaker classification, Child Vocalization Counts (CVC), Conversational Turn Counts (CTC), and Adult Word Counts (AWC). Our assessment is based on manual annotation of clips that have been randomly or periodically sampled out of daylong recordings, collected from (a) populations similar to the system's original training data (North American English-learning children aged 3-36 months), (b) children learning another dialect of English (UK), and (c) slightly older children growing up in a different linguistic and socio-cultural setting (Tsimane' learners in rural Bolivia). We find reasonably high accuracy in some measures (AWC, CVC), with more problematic levels of performance in others (CTC, precision of male adults and other children). Statistical analyses do not support the view that performance is worse for children who are dissimilar from the LENA® original training set. Whether LENA® results are accurate enough for a given research, educational, or clinical application depends largely on the specifics at hand. We therefore conclude with a set of recommendations to help researchers make this determination for their goals.

While nearly all humans eventually become competent users of their language(s), documenting the experiential context of early acquisition is crucial for both theoretical and applied reasons. Regarding theory, there are many open questions about what kinds of experiences and interactions are necessary, sufficient, or optimal for supporting language development. Moreover, the ability to accurately and quickly assess an infant's state of development at a given point in time is of central importance for clinical purposes, both for children with known risks of language delays and disorders, and those who might not be identified based on risk factors. Reliable assessments are also crucial for measuring intervention efficacy.

One approach that has been making its way into the mainstream literature across basic and applied research on language and cognition relies on day-long recordings gathered with a LENA® audiorecorder (e.g., Gilkerson

et al. 2017; Greenwood et al., 2011; Oller et al. 2010; VanDam & De Palma 2018), and further analyzed using automated, closed-source algorithms. As we summarize below, this approach has many advantages, which may explain its expanding popularity. While over a hundred papers over the past two decades have used the output automatically provided by LENA®, only a handful include validity estimates (e.g., d'Apice et al. 2019; Weisleder & Fernald 2013; Zimmerman et al. 2009), even fewer where validity estimation was the primary focus of the paper (e.g., Bulgarelli & Bergelson 2019; Busch et al. 2018; Canault et al. 2016; Ganek & Eriks-Brophy 2018; Lehet et al. 2018). As a result, few studies report sufficient details about validation accuracy for one or more metrics, limiting the interpretability of the results of a meta-analytic assessment (cf. Cristia et al. 2019). The work undertaken thus far also has some limitations, which are described further in the "Previous Validation" section below. Bearing these in mind, we endeavored to conduct an evaluation that is fully independent of the LENA® algorithms' automated assessment, permitting a systematic, extensive, and independent evaluation of its key metrics, in a large sample of diverse infants, including (a) a sample of children similar to the LENA® training set (i.e., infants and toddlers, growing up in North American English-speaking homes, and aged 3 to 36 months), (b) a group of similarly aged children learning a different dialect (UK English); and (c) slightly older children learning a different language in a very different socio-cultural setting (Tsimane'-learning children in rural Bolivia).

Brief introduction to LENA® products The LENA® system consists of hardware and software. The hardware component is a lightweight, sturdy, and easy-to-use recording device worn by a child in specialized clothing. The software is a suite of proprietary computer programs designed to provide automated quantitative analyses of the children's auditory environment and their own vocalizations. The latter was developed over an extensive corpus of full day audio recordings gathered using their patented recording hardware (Xu et al. 2009). The original dataset included over 65,000 hours of recording across over 300 American English-speaking families chosen for diversity in child age (1–42 months) and socio-economic status (Gilkerson & Richards, 2008a). Half-hour selections from 309 recordings were transcribed and annotated for the purpose of developing the algorithm, with an additional 60 min from 70 additional recordings for testing it Gilkerson et al. (2008b).

The resulting LENA® software takes as input a new audio recording and processes it incrementally in short windows, extracting a variety of acoustic features which are used to classify the audio stream into segments of at least 600 ms in length (or longer for some of the categories) using a minimum-duration Gaussian mixture model (MDGMM; Xu et al., 2009). Silence may be included to "pad" segments to this minimum duration. The segments are classified according to a set of broad speaker and non-speaker classes. The speaker classes are: Male Adult, Female Adult, "Key" Child (i.e., the one wearing the recorder) and Other Child. The non-speaker classes are: Noise, Television (including any electronics), Overlap (speech overlapped with other speech or nonspeech sounds), and Silence (SIL). With the exception of Silence, these classifications are then passed through a further likelihood test between the original classification for a given segment and the Silence class, the result of which determines whether they are "Near" (high probability of being that class) or "Far" (low probability; i.e., they may be silence instead). Given the large number of acronyms and labels of various kinds, we provide a listing of relevant LENA® abbreviations in Table 1.

After this broad speaker classification step, Female or Male Adult "Near" segments (FAN and MAN) are further processed using an adaptation of the Sphinx Phone Decoder (Lamere et al., 2003) in order to form an automated estimate of the number of words in each segment (Adult Word Count, or AWC). Key Child (CHN) segments are further processed to sub-classify regions in them into vegetative noises, crying, and speech-like vocalizations. LENA® provides counts (child vocalization count, or CVC) and durations for this last speech-like sub-segment category. A further metric,

Table 1 A partial listing of common LENA abbreviations and their meanings

Abbreviations	Meanings
FAN, MAN, CHN, CXN	Basic "meaningful speech" (near and clear speech) categories used by LENA for further processing: Female Adult Near, Male Adult Near, Key Child Near and Other Child Near categories respectively.
NON, TVN, OLN, SIL	Basic non-speech categories: Noise Near, Television Near, Overlap Near, Silence.
FAF, MAF, etc.	"Far" (low probability) versions of each Near category.
Key child	Child wearing recorder
AWC	Adult Word Count (estimated within FAN and MAN vocalizations)
CVC	Child Vocalization Count (estimated for non-cry, non-vegetative portions of CHN)
CTC	Conversational Turn Count (estimated for turns between FAN or MAN and CHN)

94 Conversational Turn Counts (CTC), reflects the number of
95 alternations between an adult and the key child (or vice
96 versa), bounded by a maximum 5s of non-speech.

Previous validation work

Q2

98 A recent systematic review (Cristia et al., 2019) found 23
99 papers containing 28 studies that reported on the accuracy of
100 the LENA® system's labels and/or derived metrics (AWC,
101 CVC, CTC). They conclude that there are:

102 "reasonably good results [overall]: over 61% for
103 recall and precision based on 11-12 non-independent
104 studies; correlations for AWC mean $r = .79$, on $n = 11$,
105 with a mean RER [what we call error rate] = 10% on
106 $n = 11$; CVC mean $r = .76$, $n = 5$, with a mean RER
107 $= 1\%$ on $n = 5$. The exception to this general trend
108 towards good performance was CTC, with a mean $r =$
109 .31, $n = 5$, RER = -64% on $n = 2$."

110 The systematic review also identified several limitations
111 of previous validation work. First, for the majority of
112 included studies, the validation component was not fully
113 evaluated by peer review. Even if the study may have
114 appeared in a peer-reviewed journal, the validation in itself
115 was often a secondary goal to support a different research
116 objective, and therefore often lacked methodological details
117 or even full results. For instance, Seidl et al. (2018) report on
118 validation of LENA® labels among children at familial risk
119 for autism in a one-paragraph appendix to the paper, which
120 only mentions confusions between female adult and child.
121 This leaves unclear whether confusions between Key child
122 and any other category (Other child, Male adult, Silence,
123 etc.) were ignored or considered to be errors. While this
124 approach may be reasonable for a given study's research
125 goals, it has the undesirable side effect of creating the
126 impression that LENA® metrics are widely validated, while
127 in fact validation methods may not have been reported or
128 evaluated in detail.

129 Second, previous studies typically did not take silence,
130 noise, or overlap into account in the reported confusion
131 matrices or other accuracy measures, particularly within
132 segments. That is, if a LENA® segment labeled "key child"
133 contained one second of silence and two seconds of speech
134 by the key child, the full three second clip may be tagged
135 as "correct" though it was only 67% correct, leading to an
136 overestimation of the accuracy of the "key child" label.

137 Third, a majority of previous validation studies used
138 the LENA® output itself to select the sections that would
139 be annotated for validation (in A. Cristia et al., 2019,
140 this held for 14/25 studies that specified the method of
141 selection). For instance, clips may have been selected
142 for manual annotation on the basis of high AWC and/or

143 CTC according to the algorithm. This unfortunately leads
144 to biased sampling: Since LENA® only counts words
145 within FAN and MAN segments and conversational turns
146 involving FAN/MAN alternations with CHN in close
147 temporal proximity, high AWC or CTC can only occur in
148 sections of the recording that are "clean" enough for the
149 algorithm to parse; otherwise, most of the section would
150 have been classified as overlap (OLN), which does not count
151 towards AWC or CTC. This would tend to bias these reports
152 toward a higher level of accuracy than would be obtained
153 across the full recording.

154 Fourth, previous validation work has typically focused
155 on a single corpus, participant population, age range,
156 and language. As a result, although considerable variation
157 in performance has sometimes been reported (Canault
158 et al. 2016; e.g., Gilkerson et al. 2016) it is difficult to
159 assess whether a numerical difference in accuracy found is
160 significant, and if so, whether this is due to a difference in
161 the way the corpus was constituted and annotated, rather
162 than on how LENA® fares with that population, age range,
163 and language.

The present work

165 We sought to assess the validity of the output provided
166 by LENA® through an approach that complements the
167 preceding literature. Specifically, we report an evaluation
168 of all speech labels, also considering non-speech labels
169 (notably silence, overlap, and TV, with limitations in our
170 approach to be discussed below); as well as the system's
171 key derived metrics: Child Vocalization Counts (CVC),
172 Conversational Turn Counts (CTC), and Adult Word Counts
173 (AWC). We aim to address several of the limitations found
174 in the body of previous work.

175 First, to maximally avoid potential bias in our annota-
176 tions, we used random or periodic sampling (detailed below)
177 to choose which sections of daylong recordings to anno-
178 tate, and did not give annotators access to the LENA®
179 output. Second, the fact that annotators did not have access
180 to the LENA® segmentation allowed an assessment of the
181 accuracy of the segmentation itself as well as categori-
182 cal labeling. Specifically, LENA® and human annotations
183 were compared every 10 ms. This allows us to capture a
184 much finer-grained representation of the auditory environ-
185 ment (i.e., if LENA® classified a 2-s audio segment as FAN,
186 but .8 s of this was actually non-speech noise or a different
187 talker, in our analysis LENA® would be credited only for
188 the proportion that was correct).

189 Third, to gain traction on generalizability, rather than
190 focusing on a single sample that either mirrors or diverges
191 from LENA®s original population, we included five
192 corpora. Three corpora sampled from the same population,
193 language, dialect, and age group the LENA® software was

developed with. A fourth corpus was chosen to allow an extension to a different dialect of English. The fifth corpus constituted an extension to a totally different recording condition (a rural setting, with large families and many children present, in a typologically different language). The age range also varies a great deal, and it is slightly higher in this last corpus. By and large, one could expect accuracy to decline in the sample of children who spoke a different English dialect compared to the three samples that matched better the data the LENA® software was developed with; and one could predict an even greater reduction in accuracy for the group that is learning a completely different language and which further mismatches in age (see other work on age- and language-mismatching samples, Busch et al. 2018, Canault et al. 2016).

Finally, the present study relies on a collaborative effort across several labs. The annotation pipeline was identical for four of the corpora, and conceptually comparable to the fifth (as detailed below). This allows us to more readily answer questions regarding differences in reliability as a function of e.g., child age and language. This approach also let us better infer the likelihood with which our results will generalize to other corpora, provided the annotation scheme is conceptually comparable.

Methods

This paper was written using RMarkDown (Baumer et al., 2014) in Team et al. (2013) running on RStudio Team (2019). It can be downloaded and reproduced using the data also available from the Open Science Framework, https://osf.io/zdg6s. These online Supplementary Materials also include a document with the full output of all models discussed here as well as additional analyses.

Corpora

The data for the evaluation comes from five different corpora, annotated in the context of two research projects. The largest one is the ACLEW project (Bergelson et al., 2017; Soderstrom et al., 2019); in this paper, we focus on four different corpora of child daylong recordings that have been pooled together, sampled, and annotated in a

coordinated manner. These four corpora are: the Bergelson corpus ("BER") from US English families from the upstate New York area (Bergelson, 2016), the LuCiD Language 0–5 corpus ("L05") consisting of English-speaking families from Northwest England (Rowland et al., 2018), the McDivitt and Winnipeg corpora ("SOD") of Canadian English families (McDivitt & Soderstrom, 2016), and the Warlaumont corpus ("WAR") of US English from Merced, California (Warlaumont et al., 2016). Some recordings in BER, and all recordings in SOD and WAR are available from HomeBank repository (VanDam et al., 2016). The second project contains a single corpus collected from Tsimane'-speaking families in Bolivia ("TSI"; Scaff et al. 2019). Socioeconomic status varies both within and across corpora. Key properties of the five corpora are summarized in Table 2.

Despite these differences, all five corpora consist of long (4–16 h) recordings collected as children wear a LENA® recorder in a LENA® vest throughout a normal day and/or night. For the four ACLEW corpora, out of the 106 recorded participants, daylong recordings from ten infants from each corpus were selected to represent a diversity of ages (0–36 months) and socio-economic contexts. In the SOD corpus, sensitive information was found in one of the files, and thus one child needed to be excluded. The tenth day for this corpus was a second day by one of the nine included children. From each daylong file, fifteen 2-min non-overlapping sections of audio (with a 5-min context window) were randomly sampled from the entire daylong timeline for manual annotation. In total, this leads to 20 h of audio, and 4.6 h of annotated speech/vocalizations (collapsing across all speaker categories).

The TSI corpus consisted of one or two recordings from 13 children, out of the 25 children recorded from field work that year; the other 12 had been recorded using other devices (not the LENA® hardware). From these files, 1-min segments were sampled in a periodic fashion. That is, for each recording, we skipped the first 33 min to allow the family to acclimate to the recorder, and then extracted 1 min of audio (with a 5-min context window) every 60 min, until the end of the recording was reached. This resulted in a total of 4.5 h of audio, and 0.7 h of speech/vocalizations (collapsing across all speaker categories).

Table 2 Key properties of the five corpora

Corpus	Children	Clips	Clip duration (seconds)	Mean Age [range] (months)	Location
WAR	10	150	120	6.3 [3-9]	Western US
BER	10	150	120	11.2 [7-17]	Northeast US
SOD	9	150	120	12.3 [2-32]	Western Canada
L05	10	150	120	20 [11-31]	Northwest England
TSI	13	272	60	34 [15-58]	Northern Bolivia

276 We chose to sample 1 or 2 min at a time (TSI, and
277 ACLEW corpora, respectively) because conversations are
278 likely to be bursty (Goh & Barabási, 2008). That is, it is
279 likely the case that speech is not produced at a periodic
280 rate (e.g., one phrase every 20 s), but rather it occurs in
281 bursts (a conversation is followed by a long period of silence
282 between the conversational partners, followed by another
283 bout of conversation, perhaps with different interlocutors,
284 followed by silence, and so on). In this context, imagine that
285 you sample a 5-s stretch. If you find speech in that stretch,
286 then it is likely you have by chance fallen on a conversation
287 bout; if you do not find speech, then you have likely found
288 a silence bout. If you were to extend that selection out
289 to several minutes, then it is likely that you will simply
290 add more material from the same type (i.e., conversation
291 bout or silence bout). As a result, any sampling method
292 that favors medium-sized stretches (5–15 min) will tend
293 to end up with samples that are internally homogeneous
294 (throughout the 5–15 min, there is a conversation, or there
295 is silence throughout). If smaller clips are sampled out, this
296 heterogeneity is still captured, but (keeping the total length
297 of audio extracted fixed) the number of clips that can be
298 extracted is larger, thus likely increasing the likelihood that
299 results will generalize to a new section of the audio.

300 In the five corpora, the 1- or 2-min samples were
301 annotated for all hearable utterance boundaries and talker

302 ID. In the ACLEW corpora, several talker IDs reflected
303 unique individual talkers, but were coded in such a way as
304 to readily allow mapping onto LENA®s talker categories,
305 e.g., key child, other child 1, female adult 1, female adult 2
306 (Bergelson et al., 2019) for the general annotation protocol;
307 cf. Casillas et al., 2017); Soderstrom et al., 2019), for an
308 introduction to the databases). The ACLEW datasets also
309 had other coding levels that will not be discussed here. In
310 the TSI corpus, only the key child and one female adult
311 whose voice recurred throughout the day were individually
312 identified, with all other talkers being classified on the basis
313 of broad age and sex into male adult, female adult, and other
314 children.

Processing

315

316 Several different time units are needed to clarify how each
317 metric is calculated (see Fig. 1). Clips refer to the 1- or
318 2-min samples extracted from recordings (TSI corpus and
319 ACLEW corpora, respectively). This is the basic unit at
320 which CVC and CTC can be established. In addition, since
321 most previous work evaluating AWC did so at the clip level,
322 we do so here as well.

323 The other metrics require a more detailed explanation,
324 conveyed graphically in Fig. 1. The stretch of time that has
325 been assigned to a speech or non-speech class by LENA®

Fig. 1 Levels at which performance is evaluated. Notice that there are multiple clips extracted from each recording; each clip can have zero or more segments; frames (10 ms) are not shown because they would be too small in this scale. Adult Word Count (AWC), Child Vocalization Count (CVC), and Conversational Turn Count (CTC) are calculated at the level of the 1- or 2-min-long audio extracts (clips). Misses, false alarms, confusions, as well as class precision and recall depend on 10-ms frames, and are totaled both at the level of individual clips and over the full audio extracts. "f" above indicates 10-ms frames. N.B. for example's sake we assume each child vocalization above has a single linguistic vocalization

is a *segment*. In one clip, there may be just one long segment (e.g., the whole clip has been assigned to Silence by LENA®); or there may be more (e.g., the first 5 s are attributed to the key child, then there is a 50-s Silence segment, and the final 5 s are attributed to a Female Adult). In the LENA® system's automated analysis, only one of these categories may be active at a given point in time. In contrast, colloquially, "utterance" or "vocalization" refers to stretches of speech detected by humans and assigned to different talkers. To be clear: in what follows, clips may have zero or more utterances. Unlike in the LENA® system, however, in the human annotation a given point in time may be associated with multiple speakers.

Given that there need not be a one-to-one correspondence between LENA® segments and human utterances, we need to define smaller time units that can be used to check for classification agreement. In this paper, we use 10 ms *frames*. This is the basic time unit used for all classification accuracy estimations, which are introduced in more detail in the next subsection.

LENA® classification accuracy Our first goal was to establish LENA® talker tag accuracy, particularly for the four broad LENA® talker categories (key child, other child, female adult, male adult; or CHN, CXN, FAN, MAN), while taking into account other categories (with some limitations on their interpretation clarified below). We calculated accuracy in two complementary ways. First, we used three frame-based standard metrics of speech and talker segmentation to allow direct comparison with other systems in the speech technology literature (False Alarm Rate, Miss Rate, Confusion Rate). We also use Identification Error Rate, which is derived by summing the first three metrics; together these provide a stringent and standard test of accuracy. Second, we used frame-based precision and recall of each category to provide an intuitive representation of the error patterns shown by this system.

Since these metrics establish errors relative to speech quantity, a problem emerges when there is no speech whatsoever in a given file. This is never discussed in the speech technology literature, because most researchers working on this are basing their analyses on files that have been selected to contain speech (e.g., recorded in a meeting, or during a phone conversation). We still wanted to take into account clips with no speech because this was central for our research goals: We need systems that can deal well with long stretches of Other (i.e., non-speech or silence), because we want to measure in an unbiased manner how much speech (and silence!) children hear. Unfortunately, in the 30% of clips that had no speech whatsoever, the false alarm, miss, and confusion rates are all undefined, because the denominator is zero. To be able to take clips with no

speech into account, we defined the following rules. First, if a clip had no speech according to the human annotator, while LENA said there was speech, then the false alarm rate was 100%, and the miss and confusion rates were zero. Second, if on the contrary, both the human annotator and LENA said there was no speech, then all the error rates were zero. Notice that when the denominator is very small because there is very little speech, the ratio for these two metrics ended up being a very large number, resulting in what may be outliers.

Speech and talker segmentation metrics The original coding was converted using custom-written python scripts into a standard adaptation of the "Rich Transcription Time Mark" (rttm) format (Ryant et al., 2019), which indicates, for each vocalization or segment, its start time, duration, and speaker. This representation was used in pyannote.metrics (Bredin, 2017) to compute four standard identification metrics: rate of false alarm for speech, rate of misses for speech, rate of confusion between talkers, and the derived identification error rate (IDER). These are calculated with the following formulas at the level of each clip, where FA (false alarm) is the number of frames during which there is no talk according to the human annotator but during which LENA® found some talk; M (miss) is the number of frames during which there is talk according to the human annotator but during which LENA® found no talk; C (confusion) is the number of frames correctly classified by LENA® as containing talk, but whose voice type has not been correctly identified (when the LENA® model recognizes female adult speech where there is male adult speech for instance), and T is the total number of frames that contain talk according to the human annotation:

- **F**alse **A**larm rate = FA/T (T=**T**otal # of frames that contain talk),
- **M**iss rate = M/T,
- **C**onfusion rate = C/T,
- **ID**entification **E**rror **R**ate (IDER) = (FA+M+C)/T

In the human annotation, there is no class representing overlapping speech as such. For the sake of completeness and ~~greater~~ comparison with the LENA® model, if two or more different sources were active at the same time according to the human annotators, these frames have been mapped to the class "overlap" post hoc. This allows us to compare this Overlap class to the LENA® system's OLN (and, for the precision/recall analysis introduced next, OLF).

However, our overlap category is not defined identically to the LENA® overlap category. For LENA®, overlap between any two categories is labeled OLN—i.e., Noise + CHN would be counted towards overlap as would FAN+FAN; whereas for us, only overlap between two

sources (e.g., key child and female adult, key child and electronic speech; but not key child + noise since noise was not coded) counts as overlap. Similarly, the TVN LENA® class is not equivalent to the electronic speech tag in the ACLEW coding, because the former also includes music, singing, crowd noise and any other sound coming from a TV or another electronic source, whereas the latter only includes speech from an electronic source. Therefore, Table 3 mentions some correspondences, but since these are not perfect, additional analyses map overlap and electronic classes onto "Other" post hoc, so as to not penalize LENA® due to a divergence in coding criteria.

Precision and recall This evaluation looks in more detail at the pattern of errors, by assessing how LENA® and human annotators agreed and disagreed. In both precision and recall, the numerator is the intersection between a LENA® tag and a human tag (e.g., the number of frames that LENA® classified as CHN and the annotator classified as Key child). The denominator differs: To calculate precision, we divide that number by the total number of frames attributed to a category by LENA®, whereas for recall, we divide by the total number of frames attributed to a category by the human annotator.

Agreement When two or more annotators provide data on the same classification, one can calculate agreement. We report on Cohen's κ as a measure of the extent to which LENA® and human annotators coincide in their labeling.

CVC and CTC evaluation

From the human annotation, each vocalization by the key child counted towards the total Child Vocalization Count (CVC) for a given clip if and only if the vocalization had been annotated as being linguistic (canonical or non-canonical in the ACLEW notation).[1] For the Conversational Turn Count (CTC), a sequence of key child and any adult (or vice versa) within 5 seconds counted towards the clip total CTC. The Pearson correlation across LENA® and human estimations was then calculated.

Users may also wish to interpret the actual number of vocalizations or turns found by LENA®. Therefore, it is important to also bear in mind errors, error rates, and absolute error rates. Despite the similarity in their names, these three metrics provide different information. We define *error* as follows: given a LENA® estimate, how close the human-generated value is. This is calculated as NL-NH, where NL is the number according to LENA® and NH is the number according to humans; this is done separately for each clip. By averaging across clips, we then get an idea of the bias towards overestimation (if this number is positive) or underestimation (if this difference is negative).

In contrast to *error*, *error rate* computes this bias in relation to the actual number of vocalizations tagged by the human coder: (NL-NH)/NL. For instance, imagine that we find that LENA® errs by 10 vocalizations according to the average error; this means that, on average across short clips like the ones used here, the numbers by LENA® would be off by ten vocalizations. By using the error rate, we can check whether this seemingly small difference is indeed small relative to the actual number found. That is, an error of ten vocalizations would be less problematic if there were 100 vocalizations on average (in which case LENA® would be just 10% off) than if there were ten (LENA® would be doubling the number of vocalizations). As with error, the sign of this difference indicates whether LENA® tends to over- or under-estimate these counts.

Finally, the *absolute error rate* is calculated with the formula abs(NL-NH)/NL, where abs indicates absolute value. As a result, it cannot be used to assess systematic under- or over-estimation biases, but rather gives an idea of how accurate the estimates are at the clip level (statistically speaking). To convey this intuitively, one could find an error of 0 together with an error rate of 0 because half of the

Table 3 Correspondence between LENA and our human annotation tags for each talker type

Talker	LENA	Human
Key Child	CHN	CHI
Other Child	CXN	OCH
Female Adult	FAN	FEM
Male Adult	MAN	MAL
Electronics	TVN*	ELE*
Overlap	OLN	OVL

Additional analyses remove one or both of the last two rows. *Electronic voices were only annotated in the ACLEW dataset. N.B. Although some Tsimane' families listen to the radio, radio speech was not annotated in the TSI corpus

---

[1]In a previous version of this analysis, we had calculated CVC as the number of CHN segments in LENA®, and the number of linguistic vocalizations as tagged by human annotators. Further inspection of LENA® documentation revealed this was incorrect, since LENA® counts can include several linguistic vocalizations within one CHN segment, and also includes linguistic vocalizations from CHF segments. Given the inaccuracy of CHF, the latter decision seems potentially problematic. The same issue affected our CTC analyses. We now present analyses here that correctly represent LENA®'s reported CVC and CTC, since these are the field-standard measures. In the Supplementary Materials (https://osf.io/zdg6s), we show results of the correlations and error analyses when CVC and CTC are calculated as the number of CHN/CHI segments instead. For CVC, the results are identical; for CTC results were slightly worse results than those reported here.

samples are -100 vocalizations off (for the error) or -100% off (for the error rates), with the other half behaving in the exact opposite fashion. The *absolute error rate* then avoids this kind of cancellation by removing the polarity (+/-) of the error.

AWC evaluation

For the AWC portion of this evaluation, we could only use transcriptions from the four ACLEW corpora, since the TSI corpus has not been transcribed (and thus lacks human word counts). Annotators for the four ACLEW corpora were proficient in the language spoken in the daylong recording, and transcribed all adult speech in keeping with minCHAT format (e.g., "wanna", not "want to", MacWhinney 2017).

One child in the (otherwise English) SOD corpus was learning French. Given our definition of orthographic words which is not language-specific, we have included this child to increase power, but results without them are nearly identical. See online Supplementary Materials, https://osf.io/zdg6s, for analyses excluding this child. In addition, a total of nine clips from three different WAR children contained some Spanish. Since we are uncertain of how accurate the transcriptions are for Spanish sentences, these clips were removed from consideration altogether.

Human AWC were determined by counting all unambiguously transcribed words spoken by adult talkers. This was achieved by first discarding all non-lexical transcript entries such as non-linguistic communicative sounds, paralinguistic markers, and markers indicating incomprehensible speech. In addition, all utterances from the key child and other children were omitted from the human AWC. The remaining orthographic entries separated by whitespaces were then counted as gold standard target words for LENA® to detect.

The 1- or 2-min clips sampled for manual annotation were not guaranteed to perfectly align with LENA® segments (i.e., talker onsets and offsets), posing a potential issue for comparing LENA® AWC relative to the human annoted word count. Of all LENA® segments found within the extracted clips, 14% straddled a clip boundary (i.e., the segment began before the clip started; or it ended after the extracted clip ended). To match LENA® AWCs with the annotated word counts, words from these straddling LENA® segments were included proportionally. That is, if 10% of the duration of a LENA® segment fell within a clip, 10% of the LENA® AWC estimate for that segment was included in the LENA® word count estimate for that clip. AWC was evaluated using Pearson correlations and error analyses, similarly to CVC and CTC.

Results

Before starting, we provide some general observations based on the manual human annotations. The "Other" category (meaning no speech, potentially silence but also non-human noise) was extremely common, constituting 71% of the 10-ms frames. In fact, 30% of the 1 to 2-min clips contained no speech by any of the speaker types (according to the human annotators). As for speakers, female adults made up 10% of the frames, the child contributed to 7%, and male adult voices, other child voices, and electronic voices were only found in 3% of the frames each. Overlap made up the remaining 3% of frames. The following consequences ensue. If frame-based accuracy is sought, a system that classifies every frame as Other (i.e., absence of speech) would be 71% correct. This is of course not desirable, but this fact highlights that systems well adapted to this kind of recording should tend to have low false alarm rates, being very conservative as to when there is speech. If the system does say there is speech, then a safe guess is that this speech comes from female adults, who provide a great majority of the speech, nearly 1.5 times as much as the key child and 2 times more than other children or male adults. In fact, given that speech by male adults and other children is relatively rare, a system that makes a lot of mistakes in these categories may still have a good global performance, because males and other children jointly accounted for only 6% of the frames (Table 4).

LENA® classification accuracy: False alarm, miss, confusion rates The analysis that yields the best LENA® performance (Table 5, Speakers) focuses on the clean human speaker categories while mapping electronic voices and overlap in the human annotation onto Other, so that the categories considered in the human annotation are FEM, MAL, CHI, OCH, alongside using only CHN, FAN, MAN, and CXN as speakers in the LENA® annotation, (with all "far" categories, TVN, and OLN all mapped onto Other; see Tables 1 and 3). Calculated in this way, LENA®'s *false alarm* rate (i.e., tagging a speech category when there was

Table 4 Number of frames, percentage of frames, and number of minutes attributed to each category by the human annotators

	Frames	Percentage	Minutes

Table 5 False Alarm Rate (FAR), Miss Rate (MR), Confusion Rate, and total Identification Error Rate (IDER, sum of the medians of the other three categories), as a function of which categories are considered

	Overall				Mean				Median			
	FAR	MR	CR	IDER	FAR	MR	CR	IDER	FAR	MR	CR	IDER
Speakers	13	56	11	79	26	39	12	73	6	39	8	73
+ Electronic	44	24	38	106	86	20	36	132	20	12	35	88
+ Overlap	58	22	42	122	126	17	42	172	30	9	41	98

Speakers indicates that only speaker categories are considered (all others are mapped onto Other); + Electronic that also electronic was scored; + Overlap that electronic and overlap in both human and LENA annotations were also scored. To be maximally informative, we report results in three ways: (1) weighted by speech: Overall false alarm, miss, and confusion rates over all clips together, thus giving more weight to clips with more speech; (2) equal weight per clip: means across clips, which represent central tendency when giving equal weight to clips with more versus less or no speech; and (3) accounting for potential outliers: since means are not robust to outliers, we also report the median across all clips

none) and *confusion* rate (i.e., providing the wrong label) were lowest. Notably, however, the *miss* rate (i.e., the system returns a judgment that no sound label is activated) was double that found with the other analysis alternatives.

In the second-best performing case (Table 5, +Electronic), overlap found in the human annotation is still mapped onto Other but Electronic voices are not, so that the human categories considered were CHI, FEM, MAL, OCH, and ELE; and the LENA® categories considered were CHN, FAN, MAN, CXN, and TVN (with all "far" classes and OLN mapped onto Other).

Finally, performance was worst when we included also overlapping regions (Table 5, +Overlap), such that the human categories considered were CHI, FEM, MAL, OCH, overlap, and electronic; and the LENA® categories considered were CHN, FAN, MAN, CXN, OLN, and TVN. It is likely that these differences are partially due to OLN and TVN not being defined similarly across the LENA® system and human annotators.

LENA® classification accuracy: Precision and recall By now, we have established that the best performance emerges when "far" labels such as CHF and OLF are mapped onto Other, as are TVN/ELE and OLN/OVL. False alarm, miss, and confusion rates are informative but may be insufficient for our readers for two reasons. First, these metrics give more importance to correctly classifying segments as speech versus non-speech (false alarms + misses) than confusing talkers (confusion). Second, many LENA® users are particularly interested in the key child. The metrics reported thus far do not give more importance to certain classes (such as key child), and they do not give us insight into the patterns of error made by the system.

We therefore turn to precision and recall. Looking at precision of speech categories is crucial for users who interpret the LENA® system's estimated quantity of adult speech or key child speech, as low precision means that some of what LENA® called e.g., key child was not in fact the key child, and thus it is providing overestimates. Looking at recall may be most interesting for users who intend to employ LENA® as a first-pass annotation: the lower the recall, the more is missed by the system and thus cannot be retrieved (because the system labeled it as something else, which will not be inspected given the original filter).

This subsection shows confusion matrices, containing information on precision and recall, for each key category. For this analysis, we collapsed over all human annotations that contained overlap between two classes into a category called "overlap". Please remember that this category is not defined the same way as the LENA® overlap category. For LENA®, overlap was a trained class, and annotators had tagged overlap between two speakers of the same kind (e.g., two female adults) as well as overlap between any of the non-speech classes they were coding (e.g., overlap between noise and TV). We also define overlap as two active classes activated at the same time, but only speech (human or electronic) has been tagged, and can count as overlap in the human annotation.

LENA® classification accuracy: Precision We start by explaining how to interpret one cell in Fig. 2: Focus on the cross of the human category (i.e., row) FEM and the LENA® category (i.e., column) FAN; when LENA® tagged a given frame as FAN, this corresponded to a frame tagged as being a female adult by the human 60% of the time. The remaining 40% of frames that LENA® tagged as FAN were actually other categories according to our human coders: 18% were Other (i.e., absence of speech), 10% were in regions of overlap between speakers or between a speaker and an electronic voice, and 12% were confusions with other speaker tags. Inspection of the rest of the confusion matrix shows that FAN and CHN are the LENA® tags with the greatest precision (setting aside the Other class, i.e., lack of speech).
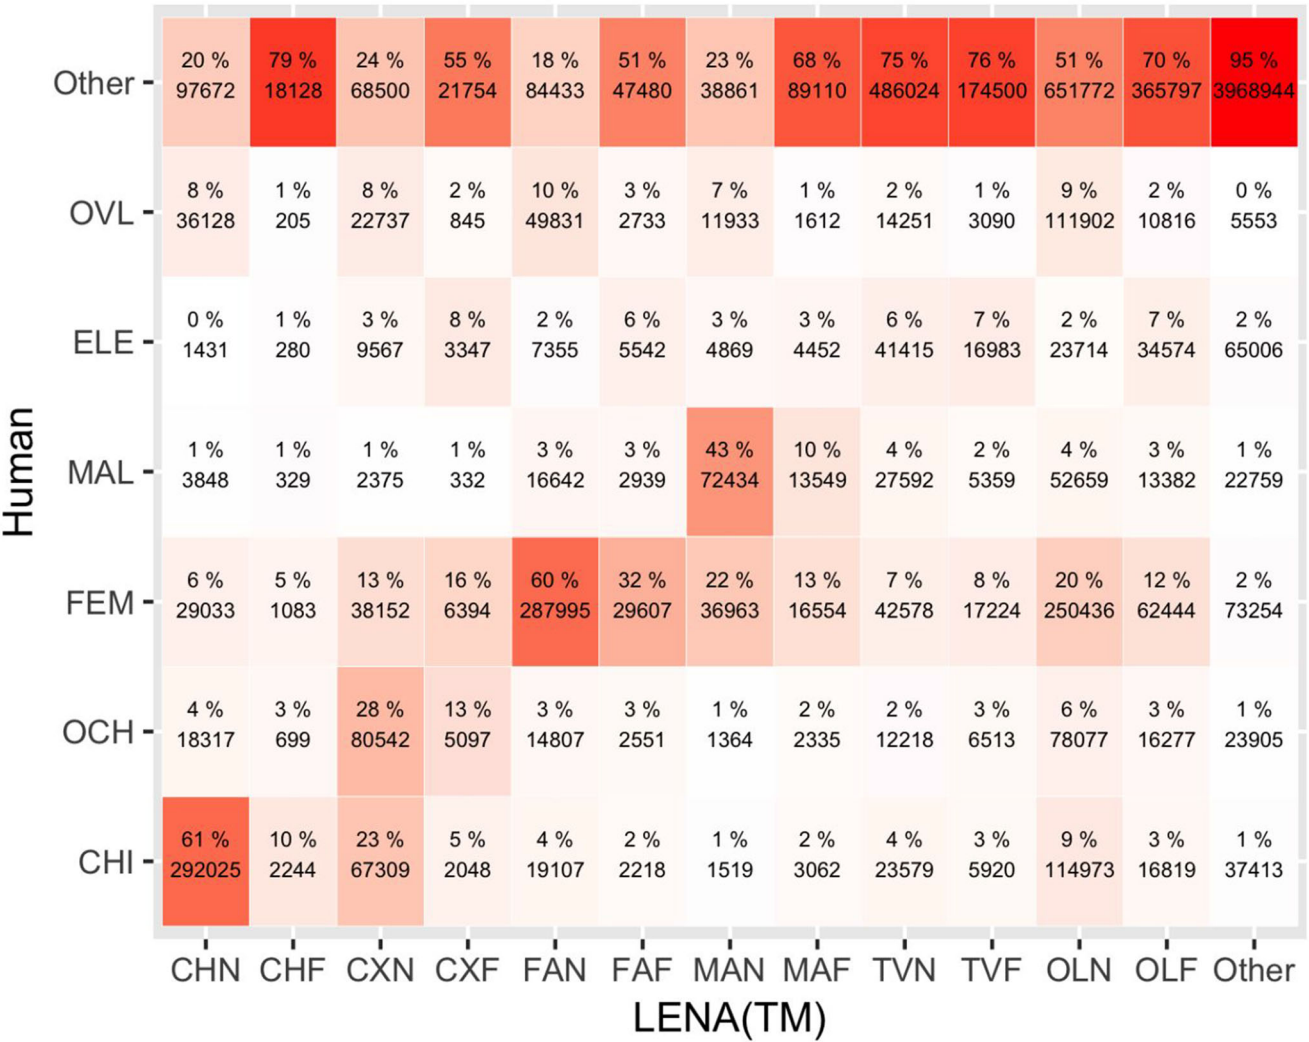

Fig. 2 Precision: Confusion matrix between LENA (*x*-axis) and human annotations (*y*-axis). In each cell, the top number indicates the percentage of all frames in that LENA category (*column*) that are labeled as a given class by the human (*row*); cells in a given column add up to 100%. The number below indicates number of frames in that intersection of LENA and human classes

662 Indeed, precision for CHN is almost identical, at 61%; 663 thus, over half of the frames labeled as the key child are, in 664 fact, the key child. The majority of the frames that LENA® 665 incorrectly tagged as being the key child are actually Other 666 (that is, silence or more generally lack of speech) according 667 to the human annotator (20%), with the remaining errors 668 being due to confusion with other categories. About 6% of 669 them are actually a female adult; 4% are another child, and 670 8% are regions of overlap across speakers, according to our 671 human coders.

672 Lower precisions are found for MAN (43%) and CXN 673 (28%). The pattern of ~~confusion~~ is somewhat different 674 from the other two categories we looked at, due to greater 675 confusion with the other label within the same age class. 676 That is, 22% of the frames LENA® tagged as being MAN 677 actually corresponded to female adult speech according to 678 the human annotation. It was also not uncommon to find a

CXN tag for a frame human listeners identified as a female 679 adult (13%), but even more confusions involved the key 680 child (28%). In a nutshell, this suggests increased caution 681 before undertaking any analyses that rely on the precision 682 of MAN and CXN, since most of what is being tagged with 683 these talker codes by LENA® is other speakers or Other 684 (i.e., silence, absence of speech). 685

Another observation is that the "far" tags of the speaker 686 categories do tend to more frequently coincide with regions 687 where humans did not detect speech (i.e., Other; 67%) than 688 the "near" tags (35%), and thus it is reasonable to exclude 689 them from consideration for most purposes. 690

The relatively high proportion of near LENA® tags that 691 correspond to Other (i.e., absence of speech) regions (range, 692 18–75%) could be partially due to the fact that the LENA® 693 system, in order to process a daylong recording quickly, 694 does not make judgments on short frames independently, 695

but rather imposes a minimum duration for all speaker categories, padding with silence in order to achieve it. Thus, any key child utterance that is shorter than .6 s will contain as much silence as needed to achieve this minimum (and more for the other talker categories). Our system of annotation, whereby human annotators had no access whatsoever to the LENA® tags, puts us in an ideal situation to assess the impact of this design decision. That is, any manual annotation that starts from the LENA® segmentation would likely bias the human annotator to ignore such interstitial silences to a greater extent than if they have no access to the LENA® tags. We inspected how often this padding by the LENA® system occurred and found that it was quite common: About half of the key child's linguistic and non-linguistic vocalizations tagged in any given clip were shorter than 600 ms long, and thus, if

alone, would have been padded by LENA® with silence automatically.

These precision analyses shed light on the extent to which the LENA® tagged segments contain what the speaker tag name indicates, relative to human coders. We now move on to *recall*, which indicates a complementary perspective: how much of the original annotations humans attributed to a given class was captured by the corresponding LENA® class.

LENA® classification accuracy: Recall Again, we start with an example to facilitate the interpretation of Fig. 3. As seen at the intersection of human CHI (last row) and LENA® CHN (first column), the best performance for a talker category for recall is CHN: 50% of the frames humans tagged as being uttered by the key child were captured by

Fig. 3 Recall: Confusion matrix between LENA (*x*-axis) and human annotations (*y*-axis). In each cell, the top number indicates the percentage of all frames that a human labeled as a given class (*row*) which were recovered in a given LENA category (*column*); cells in a given row add up to 100%. The number below indicates number of frames in that intersection of LENA and human classes

the LENA® under the CHN tag. Among the remainder of what humans labeled as the key child, 11% was captured by the LENA® system's CXN category and 20% by its OLN tag, with the rest spread across several categories.

This result suggests that an analysis pipeline that uses the LENA® system to capture the key child's vocalizations by extracting only CHN regions will get half of the key child's speech. If additional manual human vetting is occurring in the pipeline, researchers may find it fruitful to include segments labeled as CXN, since this category actually contains a further 11% of the key child's speech. Moreover, as we saw above, 28% of the CXN LENA® tags corresponds to the key child, which means that human coders re-coding CXN regions could filter out the 72% that do not, if finding key child speech were a top priority.

Many researchers also use the LENA® as a first pass to capture female adult speech through the FAN label. Only 32% of the female adult speech can be captured this way. Unlike the case of the key child, missed female speech is classified into many of the other categories, and thus there may not exist an easy solution (i.e., one would have to pull out all examples of many other categories to get at least half of the original female adult). However, if the goal is to capture as much of the female speech as possible, a reasonable solution would be to include OLN regions, since these capture a further 28% of the original female adult speech and, out of the OLN tags, 20% are indeed female adults (meaning that if human annotators are re-coding these regions to find further female adult speech, they would filter out 80% of the segments, on average).

For the remaining two speakers (MAL, OCH), recall averaged 31%, meaning that a third of male adult and other child speech is being captured by LENA®. In fact, most of these speakers' contributions are being tagged by LENA® as OLN (mean across MAN and CXN 26%) or TV (mean across MAN and CXN is 10%), although the remaining sizable proportion of misses is actually distributed across many categories.

Finally, as with precision, the "far" categories show worse performance than the "near" ones. It is worth noting that it is always the case that a higher percentage of frames is captured by the near rather than the far labels. For instance, out of all frames attributed to the key child by the human annotator, 50% were picked up by the LENA® CHN label whereas essentially 0% were picked up by the LENA® CHF label. This result provides further support that when sampling LENA® daylong files using the LENA® software, users likely need not take the "far" categories into account.

LENA® classification accuracy: Agreement using Cohen's κ Given results above suggesting that our coding of electronics may not have coincided with the LENA® system's, and that "far" categories are inaccurate, in this analysis we only consider the following labels for LENA®: CHN, FAN, MAN, and CXN (all others are collapsed into an Other category); and the following labels for human annotators: FEM, MAL, CHI, OCH (all others are collapsed into an Other category). This analysis revealed a Cohen's κ estimated at K(8580000) = 0.44, weighted κ estimated at K(8580000) = 0.46.

Fig. 4 Child Vocalization Counts (CVC), Conversational Turn Counts (CTC), and Adult Word Counts (AWC) according to LENA (*x*-axis) and humans (*y*-axis). Each *point* represents the counts totaled within a clip. The *solid line* corresponds to a linear regression fit to data from all clips; the *dashed line* corresponds to an analysis excluding clips where both the human and LENA® found zero counts. The *x* and *y* ranges have been adjusted to be equal regardless of the data distribution

Table 6 Number of clips (N) and corresponding Pearson's *r* coefficient for CVC, CTC, and AWC

	N all	r all	N	r
CVC	757	0.728	343	0.613
CTC	757	0.567	206	0.351
AWC	589	0.762	301	0.698

'N all' and 'r all' are computed over all clips. 'N' and 'r' represent non-null clips only (i.e., having some vocalizations, turns, and adult words, respectively)

Derived counts' accuracy

The accuracy of derived counts (CVC, CTC, AWC) is represented graphically in Fig. 4, statistics are provided in Table 6, and error metrics in Table 7.

For CVC, there is a strong association between clip-level counts estimated via the LENA® system and those found in the human annotation, which is not much affected when only clips with some child speech (i.e., excluding 345 clips with 0 counts in both LENA® and human annotations) were considered. This suggests that the LENA® system captures differences in terms of number of child vocalizations across clips rather well. The error analyses reveal that, generally speaking, LENA® has a slight tendency to underestimate vocalization counts. This underestimation, however, is not systematic, and cumulating errors using the absolute error rate suggests that the deviation from the actual counts might be quite significant.

As for CTC, the association between clip-level LENA® and human CTC was weaker than that found for CVC, particularly when only clips with some child speech (i.e., excluding 208 clips with 0 counts in both LENA® and human annotations) were considered. Inspection of errors and error rates reveals that LENA® tends to underestimate turn counts. As with CVC, the bias varied across clips leading to a substantial cumulative absolute error rate.

The association between clip-level LENA® and human AWC in the four English-spoken corpora was strong, even when only clips with some adult speech (i.e., excluding 303 clips with 0 counts in both LENA® and human annotations) were considered. This suggests that the LENA® system captures differences in terms of number of AWC across clips well. Error analyses for AWC reveal a different pattern from before, as the system exhibits a slight tendency to over-estimate AWC. However, this trend was inconsistent, leading to the highest absolute error rate metric among the three derived counts.

Effects of age and differences across corpora

The preceding sections include overall results collapsing across corpora. However, it is possible that performance would be higher for the corpora collected in North America (BER, WAR, SOD) than those collected in other English-speaking countries (L05) or non-English speaking populations (TSI). Additionally, our age ranges are wide, and in the case of TSI children, some of the children are older than the oldest children in the LENA® training set. To assess whether accuracy varies as a function of corpora and child age, we fit mixed models. We report on key results here; for the full model output and additional analyses, please refer to our online Supplementary Materials (https://osf.io/zdg6s).

Are there differences in false alarm, miss, and confusion rates as a function of corpus and child age? Figure 5 represents identification error rate as a function of age and corpus for individual children. To test the possible impact of age and corpus statistically, we predicted false alarm, miss, and confusion rates in the analysis with all "Far" categories, TVN/ELE, and OLN/OVL mapped onto Other (which yielded the best results in Section "False alarms, misses, confusion" above.) Our predictors were corpus, child age, and their interaction as fixed effects, and child ID as a random effect. We followed up with a Type III ANOVA to assess significance.

Corpus, child age, and their interaction were never significant, with the exception of confusion, where the interaction between corpus and age was significant at $\alpha=.05$. To investigate this effect further, we fit a mixed model

Table 7 Mean (range) for each type of error estimate for CVC, CTC, and AWC

	E	(range)	E-0	(range)	ER %	(range)	AER %	(range)
CVC	−3	(−37,14)	−6	(−35,14)	−39	(−100,650)	74	(0,650)
CTC	−2	(−41,15)	−5	(−41,15)	−29	(−100,1200)	94	(0,1200)
AWC	−1	(−211,157)	−1	(−211,157)	54	(−100,7400)	124	(0,7400)

Error estimates are: E (error; NL-NH, where NL means the count according to LENA and NH the count according to the human), E-0 (error excluding clips with a zero count according to human or system analysis), ER (error rate; (NL-NH)/NH*100, in percent of the total), and AER (absolute ER; abs(NL-NH)/NH*100, in percent of the total, with abs meaning that we take the absolute); ER and AER exclude clips where the human count is zero
Fig. 5 Identification error rate as a function of corpus and child age. Each *point* represents the median over all clips extracted from the data of one child. *Color* and shape indicates corpus: BER in *blue circles*, L05 is *green triangles*, SOD in *black squares*, TSI in *gray pluses*, and WAR in *purple crossed squares*. A number of the children had a median identification error rate of zero due to the fact that they had many clips in which there was no speech, and LENA had no false alarms, pulling the median to zero

851 predicting confusion rates from child age as fixed and
852 child ID as random effects on each corpus separately. This
853 revealed a main effect of age for SOD only (Chisq (1) =
854 14.53, p = < .001; all other chi-squares were smaller than
Q5
855 14.53, p > .120) (Table 8).

856 **Are there differences in CVC accuracy as a function of corpus**
857 **and child age?** For CVC, we fit a mixed model where
858 manually annotated CVC was predicted from LENA®
859 CVC, in interaction with corpus and age, as fixed factors,
860 and child ID as a random effect. Results are summarized
861 in Table 9 (for CVC, CTC, and AWC). Only effects and
862 interactions involving the LENA® predictor are relevant to
863 the present work, and will be discussed here. A Type III
864 ANOVA found a main effect of LENA® CVC, because this
865 was a good predictor of the human CVC.

866 **Are there differences in CTC accuracy as a function of corpus**
867 **and child age?** For CTC, we fit a mixed model where
868 CTC according to the human was predicted from CTC
869 according to LENA®, in interaction with corpus and age,
870 as fixed factors, declaring child ID as a random effect.
871 ~~This time~~ our Type III ANOVA found a main effect of the
872 LENA® CTC estimates, ~~as well as an~~ interaction ~~between~~
873 ~~this factor and corpus. We followed up on this by fitting a~~
874 ~~model where CTC according to the human was predicted~~
875 ~~from CTC according to LENA®~~ ~~as fixed and child ID as~~
876 ~~random factor, for each corpus separately. Inspection of~~
877 ~~these results (full output available from the Supplementary~~

878 ~~Materials, https://osf.io/zdg6s) suggests that the interaction~~
879 ~~emerged because the predictive value of LENA®'s CTC~~
880 ~~with respect to human counts was stronger for some corpora~~
881 ~~(Chi-squares for ROW 174.71, BER 107.49, and TSI 99.80)~~
882 ~~than others (Chi-squares for WAR 57.29, and SOD 30.91;~~
883 ~~all degrees of freedom are 1, and p < .001).~~

884 **Are there differences in AWC accuracy as a function of**
885 **corpus and child age?** Finally, for AWC (which was only
886 analyzable for the four ACLEW corpora), we fit a mixed
887 model where AWC according to the human was predicted
888 from AWC according to LENA®, in interaction with corpus
889 and age, as fixed factors, declaring child ID as random
890 effect. The Type III ANOVA revealed, in addition to a main
891 effect of the LENA® AWC estimates, a three-way and
892 both two-way interactions involving the LENA® predictor,
893 which were investigated by fitting additional mixed models
894 to each corpus separately. An interaction between LENA®
895 AWC and age was found for BER/WAR as well as SOD,
896 due to a *decreased* predictive value of the LENA AWC with
897 respect to the human AWC for older infants in BER and
898 WAR but an *increase* with age in SOD. However, it should
899 be noted that the association between LENA and human
900 AWC was significant and positive for all four corpora.

901 ## Discussion

902 The aim of the present study was to assess LENA® accu-
903 racy across key outcome measures: speaker classification
904 accuracy, Child Vocalization Counts (CVC), Conversational
905 Turn Counts (CTC), and Adult Word Counts (AWC). We
906 did this using an approach that sought to avoid inflating
907 accuracy estimates in several ways. Methodologically, we
908 used random or periodic sampling to select portions of
909 the files for manual annotation, and our human annota-
910 tors did not see the LENA® segmentation. Analytically, we
911 considered both speech and non-speech classes (including
912 electronic sounds and silence/Other). This permitted a sys-
913 tematic, extensive, and independent evaluation of LENA®'s
914 key automated metrics. We also tested generalizability by
915 analyzing LENA®'s performance across five different cor-
916 pora: three based on the same population, language, dialect,
917 and age group that LENA® was established for, and trained
918 on (North American English); one that allowed us to test
919 how accurately it captured a different dialect of English (UK
920 English); and one that tested its performance in a totally
921 different recording situation (a rural setting with large fam-
922 ilies and many children present, speaking a linguistically
923 unrelated language, and where the key children were, on
924 average, somewhat older). We begin by recapping our key
925 results.

926 Our first set of analyses tested overall accuracy, using
927 established speech and talker segmentation metrics (false

928 alarm rate, miss rate, confusion rate, and the composite
929 identification error rate), and evaluated the pattern of errors
930 in more detail, by assessing how LENA® and human
931 annotators agreed (precision and recall). We observed
932 a rather high miss rate (missing or excluding speech
933 that was there; 56, 24, and 22%). The false alarm rate
934 (identifying non-speech/silence as speech; 13, 44, and 58%)
935 and confusion rate (identifying voice type; 11, 38, and 42%)
936 were low. The overall identification error rate (which sums
937 across the three error rates) was relatively high (global 79,
938 106, and 122%).

939 To put these numbers in context, we asked the ACLEW
940 project members to share with us preliminary results of
941 their ongoing inter-rater reliability study. This study covers
942 six corpora, including the four ACLEW corpora used
943 here. For their reliability analyses, they considered the
944 "gold" to be the original complete annotations, and the
945 "system" the reliability annotations, which were done later
946 and in only a subset of the corpus (one minute per day-
947 long recording, for a total of 60 min across their six
948 corpora). While we cannot report on these results in full
949 because their publication is intended elsewhere, we can
950 state the following overall observations. Among two human
951 annotators, the ACLEW team reported an identification
952 error rate of 56% (due to 20% false alarms, 19% miss rates,
953 and 17% of confusion); for the four databases included
954 here, the average identification error rate was 47%. This
955 is considerably lower than the identification error rates
956 reported for LENA® here (best case scenario yielding an
957 identification error rate of 79, ~~106, and 122~~%), mainly
958 due to ~~a~~ much lower miss rates, whereas both false alarm
959 rates and confusion rates are higher across the two human
960 coders. Inspection of false alarms and misses suggests
961 the disagreement across humans emerges when there is
962 background speech, that one coder may pick up on and not
963 the other.[2]

964 Another question is how LENA® fares compared to
965 other automatic systems. Our thorough review of the liter-
966 ature revealed that no previous report is comparable: Most
967 often, the data used is considerably different (and overall
968 easier; e.g., recorded in formal settings, with a small num-
969 ber of speakers, who produce long vocalizations); more-
970 over, previous research tends to overestimate performance
971 by using lax evaluation criteria (e.g., allowing errors in
972 a "collar" around each vocalization). The most compara-
973 ble data point comes from the DIHARD Challenge (Ryant
974 et al., 2019). DIHARD employed data from a range of
domains, including daylong recordings; in fact, they used a

---

[2] Taking all categories together, Cohen's κ agreement was .64
(weighted κ .65) for the ACLEW inter-rater reliability coding on all
six ACLEW datasets, which is higher than the best case scenario for
LENA (.46).

different selection of data from the BER corpus used here. The subset of BER used for DIHARD is likely to lead to lower error rates because they selected only files that contained some speech; by excluding files with little to no speech, they prevent the appearance of very high diarization error rates (which emerge when the numerator, i.e., the amount of speech, is very small). Thus, the DIHARD reanalyses are likely to overestimate the systems' performance in terms of data selection. Their evaluation, however, was as strict as ours, with no leeway or collar. Diarization error rates for the BER subset by systems submitted to DIHARD 2019 varied between 48% and 121%, with a median around 70%. Thus, LENA® is competitive with respect to state-of-the-art systems, although some of them do score considerably better.[3]

Returning to the LENA® system results, the overall error rate can be fruitfully interpreted by considering performance on individual speaker tags. In terms of precision (to what extent do LENA® tags contain what they say they contain), the system performed relatively well at identifying female voices (60% of frames tagged by LENA® as FAN were coded as female adult by the human coders), and the target child (61% of frames tagged by LENA® as CHN were correct). However, the system performed substantially worse with other talker types (e.g. 43% and 28% for MAN and CXN, respectively); that is, less than a half of the frames that LENA® tagged as being speech spoken by these speakers actually correspond to them. To get a sense of how these results compare to multiple human coders, we also asked about precision and recall in the reliability data from the ACLEW team. Across all six corpora, precision for key child was the highest, at 80%; for the other speakers it was: 72% female adult, 72% male adult, and 65% other child. Precision is higher and more similar across speaker types in the ACLEW reliability data than in our LENA®-human comparison here.

In terms of recall (how accurately LENA® captured the human annotations), performance for the key child's vocalizations was moderately robust: 50% of the frames humans attributed to the key child were captured by LENA® under the CHN tag. However, recall was poorer for the other three talker types, at around 31-32%. As for recall in the ACLEW reliability data, the key child score was 79%; for the other speakers it was: 71% female adult, 63% male adult, and 55% other child. Thus, although we see lower recalls for male adults and other children in both, the overall

level of recall is much higher across two human coders than between LENA® and human, mainly due to LENA®'s tendency to miss speech more than humans do. This is, however, sensible for a system aimed at analyzing day-long recordings, which contain long stretches of silence.

Our second set of analyses tested the accuracy of three of the aggregated counts automatically provided by LENA®, namely CVC, CTC and AWC. We found relatively high correlations between clip-level counts estimated via the LENA® system and those from the human annotations for AWC and CVC, with weaker performance for CTC.

However, such correlational analyses do not establish whether LENA® systematically over- or under-estimates. For this we examined several types of error estimates. For overall error estimates (i.e., how far was the LENA® count from the human annotators'), the means across clips for CVC, CTC, and AWC was an encouraging -3.32, -1.85, and -1.04, respectively. These low errors were not solely due to many clips lacking vocalizations, turns, or adult words altogether, because when we exclude such clips we still get what seem to be low errors: means were - 6.46, - 5.08, and - 0.67 for CVC, CTC, and AWC, respectively.

We also put these error patterns in context by taking into account how large the counts were to begin with. Such error rates, however, are only defined for files which, according to the human, contain at least one unit (otherwise, we divide an error of a certain size by zero, which is undefined). We find error rates suggesting that LENA® counts are off by between a third or a half of the original counts. Inspection of the sign in these rates indicates that, by and large, LENA® systematically underestimates the raw counts of its main quantitative measures—particularly child vocalizations and conversational turns, and to a lesser extent, adult words, which showed more erratic error patterns. In addition, the absolute error rate analysis, which prevents under- and over-estimations from cancelling each other out, reveals rather considerable errors.

Finally, we also inspected the extent to which LENA® performance was affected by dialect, language, and child age in a final set of analyses. We would like to be tentative about the interpretation of these results, because we only have about ten children, often varying widely in age, in each corpus, with some mismatch in age range across corpora (see Table 2). This means that we did not have a great deal of power to capture true differences across corpora and that we may have some spurious effects or interactions due to chance differences.

With all these caveats in mind, we predicted that performance would be higher for the corpora collected in North America (BER, WAR, SOD) than for corpora collected in other English-speaking countries (L05) or non-English-speaking populations (TSI), and that accuracy would decrease with age, since our sample contains children

---

[3]DIHARD uses diarization error rate on individual speakers' identities, rather than identification error rates on speaker types as we do here. There is no mathematical procedure to derive one from the other, except in the case when there is one speaker per speaker type, in which case diarization error rate is most likely identical to identification error rate.

older than those included in the LENA® training set. This is not what we found. For instance, we found an interaction between corpus and age for the confusion rate, due to an increase in confusion rates for older infants within the SOD corpus but not in any of the others, a result that we have no ready explanation for, and which may be a spurious result given the sample size (ten recordings from nine children, in this corpus). Similarly, LENA® counts predicted human counts in the CVC, CTC, and AWC analyses, and although we did observe some interactions, none of them were easy to interpret and none explained away the predictive value. As just mentioned, we are cautious when interpreting these results, and invite further work on bigger samples (more data per child, more children per corpus) to ensure sufficient power and precision.

In general, whether LENA® results are "good enough" depends largely on the goals of each particular study. For example, we can describe precision rates of 60% (i.e., 60% of frames tagged by LENA® as FAN were coded as female adult by human coders) and 61% (i.e., 61% of frames tagged as target child were also tagged as such by human coders) as being reasonably good, because they are much higher than the system's precision rates for other speakers (MAN 43%, CXN 28%). Although they are lower than what may be found across two human raters, some additional level of error may be expected in an automatic system. Notice saliently that, despite having been created over a decade ago, the global performance of LENA® was competitive when compared to state of the art diarization systems. That said, whether a *particular* accuracy rate can be considered sufficient will depend on the purpose of the study. As a result, we next provide a set of recommendations to help researchers make this determination for their goals.

What research goals can one pursue given the performance of LENA® segmentation and metrics? In the present corpora, the system's false alarm rate (i.e., identifying speech where there was none) was very low while its miss rate (missing speech that was actually there) was relatively high. This makes LENA® more suitable for studies in which it is extremely important not to "invent" speech that is not there but less suitable for studies in which capturing most, if not all, of the speech produced is crucial. Based on these findings, LENA® would be a good tool for finding "high talk volume" parts of the day for a) careful further transcription (e.g., of low-frequency events like a certain grammatical construction of interest), b) annotation of specific speech characteristics (e.g., mean length of utterance), or c) comparing relative talk volume across samples. However, we advise caution in using LENA® when raw quantity of speech is crucial for the research question, or when small differences in talk volume might have very significant theoretical consequences; this is often the case in clinical populations where children's own vocalizations can be an important diagnosis-relevant characteristic (e.g., in children who are deaf or hard of hearing, individuals with ASD, speech apraxia, etc.).

Similarly, although the overall confusion rate (i.e., incorrectly identifying talkers, such as giving a "female adult" tag for a "child" utterance) for LENA® was very low, this does not fully convey the level of accuracy for speech, particularly when considering every talker type. In terms of precision, the system's female adult and key child categorization was quite accurate, whereas precision was lower for male adults and other children: the majority of the frames labeled as male adult or other children did not in fact contain speech by these speaker types. In terms of recall, LENA® was fairly good at capturing speech by the key child as such, but recall was lower for the other talker categories.

We, thus, recommend caution before undertaking any analyses that rely on the accuracy (precision and/or recall) of male adult and other children's speech. For example, if the goal is simply to calculate an overall adult word count (AWC), summing over male and female adult speakers, some confusion between MAN and FAN is likely not problematic. However, if the goal of the study is to compare the relative input from fathers and mothers, LENA® tags are relatively unreliable and in our view, merit further manual vetting in most use cases.

As another example (detailed further in the "Recall" results above), if the goal is to capture as many of the key child's vocalizations as possible, it might be worthwhile to pull out segments LENA® labeled as non-target child, CXN, (of which 23% was target child speech) as well, with human coders brought in to filter out non-target child speech. Indeed, we find that this kind of binary classification (key child or not) can be readily undertaken with little training by research assistants in our labs, and would substantially boost data quality and quantity for child vocalizations in this use case.

Notably, while we recommend LENA® users be cautious in their use of LENA® identification and classification, especially for certain talker classes, our results for LENA® count metrics suggest these derived counts may be accurate enough to serve well across a large variety of uses. To begin with, as far as it is possible to generalize from a small sample from a handful of corpora, it seems that the system does not perform a great deal worse for children who do not correspond to the LENA® training set. Moreover, *correlations* between human and LENA® clip-level counts were high, suggesting that the software accurately captures differences in counts across clips (even when *absolute error rates* were also high). Except for CTC, these correlations remained quite high even when clips with counts equal to zero were removed from consideration, suggesting that

LENA® captures gradience in vocalization and adult word counts.

However, our finding that LENA® generally underestimates the quantity of child vocalizations and child-adult turns deserves further consideration. Further work is needed to fully understand the nature and extent of this limitation. Our clips were 1–2 min in length, and therefore they either tended to have very little speech or a lot of it. Error rates over hours could be smaller, because local errors average out; or greater, if the LENA® system systematically underestimates counts. In a LENA® technical report, AWC accuracy was variable across two 12-hour recordings: 1% lower than human transcription for one child, but 27% lower for a second child. This same report notes that AWC accuracy quickly plateaus as recording time increases beyond one hour, leveling to 5-10% in recordings greater than 2 hours in length (Xu et al., 2009). If underestimates are systematic (as suggested by present results for CVC and CTC, but not AWC), it may be possible to develop a correction factor to compensate for this bias.

How to test the reliability of the automated output provided by LENA® We hope the current paper inspires others to evaluate and report all aspects of the system, rather than a subset of metrics. Similarly, extensive evaluations of LENA® in other corpora would bolster the validation literature, and be useful for the whole research community. In fact, it would be ideal if researchers systematically test the reliability of LENA® counts in their own samples, especially if they are collecting data from families living in different environments from those assessed here. Next, we provide some guidelines for how to go about this. Note that this requires downloading the audio (.wav) file generated by LENA® as well as the corresponding LENA® output file.

First, we recommend a literature search [starting from A. Cristia et al. (2019)'s a systematic review], to determine whether there exists reliability data for a similar sample. If no reliability studies exist, draw 10 x 2 min randomly from ten children. This is about 3 h, 20 min of data, which takes roughly 90 h to annotate, in our experience. We recommend training annotators using the ACLEW Annotation Scheme https://osf.io/b2jep/, which has an online test annotators can go through to ensure reliability. Once the manual annotations are complete, the LENA® annotations can be extracted and compared against the human annotation using the code we provide in supplementary materials (https://github.com/jsalt-coml/lena_eval). This will allow researchers to extract the classification accuracy measures used here (false alarm rate, miss rate, confusion rate and the derived identification error rate), as well as CVC, CTC, and AWC comparing LENA® and human annotations. We note re-using our code is only possible "off the shelf" for manual annotations made using the ACLEW Annotation Scheme,

though in principle, it is adaptable to other schemata by adept programmers.

One issue that may arise is whether data should be sampled differently to, for example, make sure every class is represented the same amount of time and/or a minimum of time. Our understanding is that class imbalance and data scarceness is an important issue for training, and directly affects algorithm accuracy (this is a general problem, but to cite just one example on GMMs, Garcia-Moral et al., 2011). However, it does not pose the same kind of problem for evaluation. That is, if there are no samples of a given category, then accuracy cannot be evaluated; if there are only a few, then it is possible that these are special in some way and accuracy estimates may not generalize well to others. Thus, it would indeed be desirable to have enough samples of a given label to reduce the impact of each individual instance, in case they are outliers. That said, almost any strategy that attempts to boost the frequency of specific categories risks worsening non-generalizability concerns. For instance, if one were to over-sample regions tagged by LENA® as MAN in the hopes of having more male samples, one may only be capturing certain types of male speech or acoustic properties. To take this example further, notice that male speech is our smallest category, representing 3% of the data. Since we sampled randomly or periodically, this represents the prevalence of male speech and the samples that are included are unlikely to be acoustically biased.

Separately, researchers should reflect on the accuracy needed for their question of interest. For instance, suppose we have an evaluation of an intervention where we expect treatment children to hear 20% more speech than controls, or an individual difference study where we expect that the lower fifth of the children hear 20% less speech than the top fifth. If the intended measure used to compare groups has an error rate larger than the effect predicted (such as the CTC error rate we find here), a different algorithm or outcome metric would be wise.

Conclusions

In conclusion, in this study, we have provided a broad evaluation of accuracy across the key outcome measures provided by LENA® (classification, Child Vocalization Counts, Conversational Turn Counts, and Adult Word Counts), in a sample of data drawn across different dialects, languages, ages, and socio-cultural settings. We have provided some recommendations for how to use LENA® in future studies most effectively, and how to test the accuracy of the LENA® algorithms on particular samples of data.

There are, however, a number of areas of research that we have not addressed. For example, we have not investigated how accurately LENA® detects individual variation across

children or families. It would be particularly useful to know whether LENA® can classify children with the sensitivity and specificity needed for accurate identification of language disorders. Oller et al. (2010) used LENA® to differentiate vocalizations from 232 typically developing children and children with autism or language delay with a high degree of accuracy. However, key to this was the use of additional algorithms, not yet available from LENA®, to identify and classify the acoustic features of "speech-related vocal islands". Further work (including shared code) would greatly bolster progress on this topic.

Even if it turns out that LENA® is not accurate enough to classify children precisely for a given ability or diagnosis, it may be accurate enough to capture the rank order of individual children's language growth, which can provide useful information about the relative language level of children in a sample or population (see, e.g., Gilkerson et al., 2017). Similarly, LENA® may not accurately capture the precise number of child vocalizations produced over time, but it may track developmental trajectory (e.g., the slope of growth) relatively well. Finally, although our results suggest that aspects of the system's output may be relatively robust to differences across languages and dialects, we need more evidence of how it fares across mono- and multi-lingual language environments (cf. Orena, 2019).

It is undeniable that children learn language from the world around them. Naturalistic daylong recordings offer an important avenue to examine this uniquely human development, alongside other fundamental questions about human interaction, linguistic typology, psychology, and sociology. Tools and approaches that allow us to tap into such recordings' contents stand to contribute deeply to our understanding of these processes. We look forward to further work that addresses the many remaining questions within this area.

Open Practices Statement The study relies indirectly on day-long audio recordings (which cannot be made public to protect participants) and human and LENA® annotations for extracted clips (which are not deidentified); these are stored in private repositories that do not have a persistent identifier. The annotation data were used to generate statistics at the clip level, which are the input to analyses presented here. Both the clip level statistics and analyses in this manuscript are publicly available from https://osf.io/zdg6s. None of these analyses were pre-registered. Additional computer code for other levels of analysis is available from https://github.com/jsalt-coml/lena_eval.

AUTHOR QUERIES

AUTHOR PLEASE ANSWER ALL QUERIES:

Q1. Please check if the affiliations are captured and presented correctly.

Q2. Please check if the section headings are assigned to appropriate levels.

Q3. Did you mean to write "annotated"? please clarify.

Q4. Missing citation for Table 4 was inserted here. Please check if appropriate. Otherwise, please provide citation for Table 4.

Q5. Missing citation for Table 8 was inserted here. Please check if appropriate. Otherwise, please provide citation for Table 8.

Q6. Please check reference 'Bergelson 2016' if captured and presented correctly.
